PETER N. IRELAND

A New Keynesian Perspective on the Great Recession

With an estimated New Keynesian model, this paper compares the “Great Recession” of 2007–09 to its two immediate predecessors in 1990–91 and 2001. The model attributes all three downturns to a similar mix of aggregate demand and supply disturbances. The most recent series of adverse shocks lasted longer and became more severe, however, prolonging and deepening the Great Recession. In addition, the zero lower bound on the nominal interest rate prevented monetary policy from stabilizing the U.S. economy as it had previously; counterfactual simulations suggest that without this constraint, output would have recovered sooner and more quickly in 2009.

JEL codes: E32, E52

Keywords: aggregate demand and supply, great recession, New Keynesian, zero lower bound.

NO MATTER WHAT happens next, this seems safe to say: the recession of 2007 through 2009 will always be remembered for its extreme severity. By many measures, in fact, it appears even now as the worst downturn the U.S. economy has experienced since the Great Depression. It brought to an abrupt close the relatively tranquil period, lasting more than 20 years, that had become known as the “Great Moderation.” And for all these reasons, it deserves a special name of its own: the “Great Recession” of 2007–09.

Indeed, the Great Recession’s extreme severity makes it tempting to argue that new theories are required to fully explain it. And given the prominence of the financial institutions whose solvency and liquidity problems grabbed and held the newspaper headlines as the broader economic crisis deepened, it is tempting to single out those solvency and liquidity problems as chief among the fundamental factors causing the recession itself.

I would like to thank Michael Belongia, Paul Evans, and an anonymous referee for extremely helpful comments and suggestions on previous drafts of this paper. The opinions, findings, conclusions, and recommendations expressed herein are my own and do not reflect those of the National Bureau of Economic Research.

PETER N. IRELAND is at Boston College, Department of Economics, and at the National Bureau of Economic Research (E-mail: irelandp@bc.edu).

Received April 19, 2010; and accepted in revised form August 26, 2010.

But while, on the bright side, the extreme volatility in financial markets and across the economy as a whole surely has generated action in the data that will be useful in extending macroeconomic theory going forward, three sets of considerations suggest that it would be premature to abandon existing models just yet. First, banking failures and liquidity dry-ups seldom occur as totally exogenous events; this time around, they stemmed from problems in real estate markets that, themselves, undoubtedly reflected more basic macroeconomic fundamentals. Attempts to explain movements in one set of endogenous variables, like GDP and employment, by direct appeal to movements in another, like asset market valuations or interest rates, sometimes make for decent journalism but rarely produce satisfactory economic insights. Second, recessions have always been accompanied by an increase in bankruptcies among financial and nonfinancial firms alike, and one recent recession, in 1990–91, also featured systemic problems in banking that wiped out the savings and loan industry as a major segment of the U.S. financial sector just as, today, the future of the investment banking industry has been thrown into doubt. And third, even granting the possibility that declines in housing prices and problems in credit markets might have played an independent, casual role behind the Great Recession's severity, it remains of interest to explore whether, in the context of a conventional, small-scale aggregative framework, such impulses ought to be interpreted as shocks to aggregate demand, working through their effects on household wealth and consumer and business confidence, aggregate supply, working through their effects on the efficiency of the distribution of productive resources, or some combination of the two.

Accordingly, this paper asks whether, in terms of its macroeconomics, the Great Recession of 2007–09 really stands apart from what came before. To answer this question, the paper examines and interprets recent data with the help of an estimated New Keynesian model, that is, within the same analytic framework that Lubik and Schorfheide (2004), Boivin and Giannoni (2006), Justiniano and Primiceri (2008), and Canova (2009), to mention just a small handful of related studies, used to consider various aspects of the Great Moderation. The focus here, however, lies entirely on the post-1983 period. Rather than comparing U.S. business cycles before and during the Great Moderation, the objective here is to compare the Great Recession of 2007–09 with its two immediate predecessors: the milder recessions of 1990–91 and 2001.

The analysis suggests, in fact, that the 2007–09 recession has its origins in a combination of aggregate demand and supply disturbances that resembles quite closely the mix of shocks that set off the previous two downturns. The main difference is that for the more recent recession, the series of adverse shocks lasted much longer and became much more severe as well. The analysis does point to another difference, however, relating to the zero lower bound on the nominal interest rate. This constraint on monetary policy became binding during the 2007–09 recession, though not before. And the estimated model suggests that because of this constraint, monetary policy became quite restrictive, especially during 2009, contributing to both the length and severity of the downturn. By contrast, expansionary monetary policy helped, at least

somewhat, in cushioning the U.S. economy against the adverse shocks that hit during 1990–91 and 2001.

Altogether, these results deepen our understanding of recent U.S. economic history. They point to systematic aspects of U.S. monetary policy that might be reconsidered in light of that recent history. And they speak to the continued relevance of the New Keynesian model, perhaps not as providing the very last word on but certainly for offering up useful insights into, both macroeconomic analysis and monetary policy evaluation.

1. THE MODEL

1.1 Overview

The particular variant of the New Keynesian model used here takes its basic features from those developed by Ireland (2004, 2007). The modeling strategy thereby follows Canova's (2009) by using a small-scale model that focuses on three main equations: the New Keynesian IS Curve, describing the behavior of a representative household; the New Keynesian Phillips Curve, describing the optimizing behavior of monopolistically competitive firms that, in this case, face explicit costs of nominal price adjustment; and a monetary policy rule—a version of the Taylor (1993) rule—describing how the central bank adjusts the short-term nominal interest rate in response to movements in output and inflation. Likewise, three variables take center stage in the empirical analysis: output, inflation, and the short-term nominal interest rate.

Relative to the simplest possible New Keynesian models, the framework used here gets enriched by introducing habit formation into the representative household's preferences, allowing for partially backward-looking behavior in the IS curve, and partial indexation into firms' price adjustment cost specification, allowing for partially backward-looking behavior in the Phillips curve. Again following Canova's (2009) strategy, the analysis here stops short of adding all of the extra features present in larger-scale New Keynesian models like Smets and Wouters' (2003), which would of course expand the model's internal dynamics still further but at the cost of complicating the macroeconomic story told by the theory and thereby placing at risk the model's ability to distill useful information out of the action contained in the data.

The model economy, therefore, consists of a representative household, a representative finished-goods-producing firm, a continuum of intermediate-goods-producing firms indexed by $i \in [0, 1]$, and a central bank. During each period $t = 0, 1, 2, \dots$, each intermediate-goods-producing firm produces a distinct, perishable intermediate good. Hence, intermediate goods may also be indexed by $i \in [0, 1]$, where firm i produces good i . The model features enough symmetry, however, to allow the analysis to focus on the behavior of a representative intermediate-goods-producing firm, identified by the generic index i . The activities of each agent, and their implications for the evolution of equilibrium prices and quantities, will now be described in turn.

1.2 The Representative Household

The representative household enters each period $t = 0, 1, 2, \dots$ with money M_{t-1} and bonds B_{t-1} . At the beginning of period t , the household receives a lump-sum nominal transfer T_t from the central bank. Next, the household's bonds mature, providing B_{t-1} additional units of money. The household uses some of its money to purchase B_t new bonds at the price of $1/r_t$ units of money per bond, where r_t denotes the gross nominal interest rate between t and $t + 1$.

During period t , the household supplies a total of h_t units of labor to the various intermediate-goods-producing firms. The household gets paid at the nominal wage rate W_t , earning $W_t h_t$ in total labor income during the period. Also during the period, the household consumes C_t units of the finished good, purchased at the nominal price P_t from the representative finished-goods-producing firm.

At the end of period t , the household receives nominal dividend payments totaling D_t , representing the profits earned by the various intermediate-goods-producing firms. The household then carries M_t units of money into period $t + 1$, where its budget constraint dictates that

$$\frac{M_{t-1} + T_t + B_{t-1} + W_t h_t + D_t}{P_t} \geq C_t + \frac{M_t + B_t/r_t}{P_t} \quad (1)$$

for all $t = 0, 1, 2, \dots$

The household's preferences are described by the expected utility function

$$E_0 \sum_{t=0}^{\infty} \beta^t a_t [\ln(C_t - \gamma C_{t-1}) + \ln(M_t/P_t) - h_t], \quad (2)$$

where both the discount factor and the habit formation parameter lie between zero and one: $0 < \beta < 1$ and $0 \leq \gamma < 1$. The preference shock a_t follows the stationary autoregressive process

$$\ln(a_t) = \rho_a \ln(a_{t-1}) + \varepsilon_{at} \quad (3)$$

for all $t = 0, 1, 2, \dots$, with $0 \leq \rho_a < 1$, where the serially uncorrelated innovation ε_{at} is normally distributed with mean zero and standard deviation σ_a . Utility is additively separable across consumption, real money balances, and hours worked so as to imply a conventional specification for the model's IS curve that, in particular, does not include additional terms involving real balances or employment. Given this additive separability, the logarithmic specification over consumption is needed, as shown by King, Plosser, and Rebelo (1988), for the model to be consistent with balanced growth. And, as noted earlier, habit formation is introduced into preferences to allow for partially backward-looking behavior in consumption.

Thus, the household chooses C_t , h_t , B_t , and M_t for all $t = 0, 1, 2, \dots$ to maximize its utility function (2) subject to the budget constraint (1) for all $t = 0, 1, 2, \dots$. The

first-order conditions for this problem can be written as

$$\Lambda_t = \frac{a_t}{C_t - \gamma C_{t-1}} - \beta \gamma E_t \left(\frac{a_{t+1}}{C_{t+1} - \gamma C_t} \right), \quad (4)$$

$$a_t = \Lambda_t (W_t / P_t), \quad (5)$$

$$\Lambda_t = \beta r_t E_t (\Lambda_{t+1} / \pi_{t+1}), \quad (6)$$

$$M_t / P_t = (a_t / \Lambda_t) [r_t / (r_t - 1)], \quad (7)$$

and (1) with equality for all $t = 0, 1, 2, \dots$, where Λ_t denotes the nonnegative Lagrange multiplier on the budget constraint for period t and $\pi_t = P_t / P_{t-1}$ denotes the gross inflation rate between t and $t + 1$.

1.3 The Representative Finished-Goods-Producing Firm

During each period $t = 0, 1, 2, \dots$, the representative finished-goods-producing firm uses $Y_t(i)$ units of each intermediate good $i \in [0, 1]$, purchased at the nominal price $P_t(i)$, to manufacture Y_t units of the finished good according to the constant-returns-to-scale technology described by

$$\left[\int_0^1 Y_t(i)^{(\theta_t-1)/\theta_t} di \right]^{\theta_t/(\theta_t-1)} \geq Y_t, \quad (8)$$

where, in equilibrium, θ_t translates into a random shock to the intermediate-goods-producing firms' desired markup of price over marginal cost and therefore acts like a cost-push shock of the kind introduced into New Keynesian models by Clarida, Gali, and Gertler (1999) and Steinsson (2003). Here, this markup shock follows the stationary autoregressive process

$$\ln(\theta_t) = (1 - \rho_\theta) \ln(\theta) + \rho_\theta \ln(\theta_{t-1}) + \varepsilon_{\theta t} \quad (9)$$

for all $t = 0, 1, 2, \dots$, with $0 \leq \rho_\theta < 1$ and $\theta > 1$, where the serially uncorrelated innovation $\varepsilon_{\theta t}$ is normally distributed with mean zero and standard deviation σ_θ .

Thus, during each period $t = 0, 1, 2, \dots$, the finished-goods-producing firm chooses $Y_t(i)$ for all $i \in [0, 1]$ to maximize its profits, which are given by

$$P_t \left[\int_0^1 Y_t(i)^{(\theta_t-1)/\theta_t} di \right]^{\theta_t/(\theta_t-1)} - \int_0^1 P_t(i) Y_t(i) di.$$

The first-order conditions for this problem are

$$Y_t(i) = [P_t(i) / P_t]^{-\theta_t} Y_t$$

for all $i \in [0, 1]$ and $t = 0, 1, 2, \dots$. Competition then drives the finished-goods-producing firm's profits to zero in equilibrium, determining P_t as

$$P_t = \left[\int_0^1 P_t(i)^{1-\theta_t} di \right]^{1/(1-\theta_t)}$$

for all $t = 0, 1, 2, \dots$.

1.4 The Representative Intermediate-Goods-Producing Firm

During each period $t = 0, 1, 2, \dots$, the representative intermediate-goods-producing firm hires $h_t(i)$ units of labor from the representative household to manufacture $Y_t(i)$ units of intermediate good i according to the constant-returns-to-scale technology described by

$$Z_t h_t(i) \geq Y_t(i). \quad (10)$$

The aggregate technology shock Z_t follows a random walk with drift:

$$\ln(Z_t) = \ln(z) + \ln(Z_{t-1}) + \varepsilon_{zt} \quad (11)$$

for all $t = 0, 1, 2, \dots$, with $z > 1$ and where the serially uncorrelated innovation ε_{zt} is normally distributed with mean zero and standard deviation σ_z .

Since the intermediate goods substitute imperfectly for one another in producing the finished good, the representative intermediate-goods-producing firm sells its output in a monopolistically competitive market: during period t , the firm sets its nominal price $P_t(i)$, subject to the requirement that it satisfy the representative finished-goods-producing firm's demand at that price. And, following Rotemberg (1982), the intermediate-goods-producing firm faces a quadratic cost of adjusting its nominal price between periods, measured in terms of the finished good and given by

$$\frac{\phi}{2} \left[\frac{P_t(i)}{\pi_{t-1}^\alpha \pi^{1-\alpha} P_{t-1}(i)} - 1 \right]^2 Y_t,$$

where $\phi \leq 0$ governs the magnitude of the price adjustment cost, α is a parameter that lies between zero and one, with $0 \leq \alpha \leq 1$, and π denotes the average, or steady-state, rate of inflation. Although less popular than Calvo's (1983) formulation of staggered price setting, this quadratic cost of nominal price adjustment gives rise to aggregate price dynamics that are very similar to those implied by Calvo's model, as shown by Rotemberg (1987) and discussed further by Ireland (2004, 2007). And, according to the particular specification used here, the extent to which price setting is backward or forward looking depends on the magnitude of the parameter α . When, in particular, $\alpha = 0$, then price setting is purely forward looking in the sense that there is no indexation of prices to past inflation rates. When, on the other hand, $\alpha = 1$, then price setting is fully backward looking, in the sense that there is complete indexation of prices to the previous period's inflation rate.

In any case, the cost of price adjustment makes the intermediate-goods-producing firm's problem dynamic: it chooses $P_t(i)$ for all $t = 0, 1, 2, \dots$ to maximize its total real market value, proportional to

$$E_0 \sum_{t=0}^{\infty} \beta^t \Lambda_t [D_t(i)/P_t],$$

where $\beta^t \Lambda_t$ measures the marginal utility value to the representative household of an additional unit of real profits received in the form of dividends during period t and where

$$\frac{D_t(i)}{P_t} = \left[\frac{P_t(i)}{P_t} \right]^{1-\theta_t} Y_t - \left[\frac{P_t(i)}{P_t} \right]^{-\theta_t} \left(\frac{W_t Y_t}{P_t Z_t} \right) - \frac{\phi}{2} \left[\frac{P_t(i)}{\pi_{t-1}^\alpha \pi^{1-\alpha} P_{t-1}(i)} - 1 \right]^2 Y_t \quad (12)$$

measures the firm's real profits during the same period t . The first-order conditions for this problem are

$$\begin{aligned} 0 = & (1 - \theta_t) \left[\frac{P_t(i)}{P_t} \right]^{-\theta_t} + \theta_t \left[\frac{P_t(i)}{P_t} \right]^{-\theta_t-1} \left(\frac{W_t}{P_t Z_t} \right) \\ & - \phi \left[\frac{P_t(i)}{\pi_{t-1}^\alpha \pi^{1-\alpha} P_{t-1}(i)} - 1 \right] \left[\frac{P_t(i)}{\pi_{t-1}^\alpha \pi^{1-\alpha} P_{t-1}(i)} \right] \\ & + \beta \phi E_t \left\{ \left(\frac{\Lambda_{t+1}}{\Lambda_t} \right) \left[\frac{P_{t+1}(i)}{\pi_t^\alpha \pi^{1-\alpha} P_t(i)} - 1 \right] \left[\frac{P_{t+1}(i)}{\pi_t^\alpha \pi^{1-\alpha} P_t(i)} \right] \left[\frac{P_t Y_{t+1}}{P_t(i) Y_t} \right] \right\} \end{aligned} \quad (13)$$

and (10) with equality for all $t = 0, 1, 2, \dots$

1.5 The Central Bank

The central bank conducts monetary policy according to a variant of the Taylor (1993) rule

$$\ln(r_t) - \ln(r_{t-1}) = \rho_\pi \ln(\pi_t/\pi) + \rho_g \ln(g_t/g) + \varepsilon_{rt}, \quad (14)$$

according to which it raises or lowers the short-term nominal interest rate whenever inflation π_t and output growth

$$g_t = Y_t/Y_{t-1} \quad (15)$$

rise above or fall below their average, or steady-state, values π and g . The policy rule (14) departs from Taylor's (1993) specification in a way that allows for a considerable degree of interest rate smoothing by including the change, as opposed to the level, of the short-term nominal interest rate on the left-hand side. Fuhrer and Moore (1995) also use a policy rule of this type in their empirical model of the U.S.

economy, while Levin, Wieland, and Williams (1999) and Orphanides and Williams (2002, 2006) show that similar “first difference” rules for interest rate setting support desirable outcomes across a wide range of macroeconomic models, including those in which the central bank and private agents are assumed to have imperfect information about the economy. When implementing a rule of the general form shown in (14), the central bank must choose the response coefficients $\rho_\pi < 0$ and $\rho_g \geq 0$ in order to guarantee the existence of a unique dynamically stable rational expectations equilibrium; the central bank must also choose its long-run target π for inflation. The serially uncorrelated monetary policy shock ε_{rt} is normally distributed with mean zero and standard deviation σ_r .

1.6 The Efficient Level of Output and the Output Gap

As preliminary step in interpreting the results from below, particularly those pertaining to the role played by Federal Reserve policy in shaping the U.S. economy’s response to the model’s preference, cost-push, and technology shocks, it is helpful to define a welfare-theoretic measure of the output gap, based on a comparison between the level of output that prevails in equilibrium and the level of output chosen by a benevolent social planner who can overcome the frictions associated with monetary trade and sluggish nominal price adjustment. Such a planner chooses the efficient level of output Q_t and the efficient amounts of labor $n_t(i)$ to allocate to the production of each intermediate good $i \in [0, 1]$ to maximize a social welfare function

$$E_0 \sum_{t=0}^{\infty} \beta^t a_t \left[\ln(Q_t - \gamma Q_{t-1}) - \int_0^1 n_t(i) di \right],$$

reflecting the same preference orderings over consumption and leisure embedded into the representative household’s utility function (2), subject to the aggregate feasibility constraint

$$Z_t \left[\int_0^1 n_t(i)^{(\theta_t-1)/\theta_t} di \right]^{\theta_t/(\theta_t-1)} \geq Q_t, \quad (16)$$

reflecting the technologies described in (8) and (10) for producing the finished good using the intermediate goods and the intermediate goods using labor, for all $t = 0, 1, 2, \dots$.

The first-order conditions for this social planner’s problem can be written as

$$\Xi_t = \frac{a_t}{Q_t - \gamma Q_{t-1}} - \beta \gamma E_t \left(\frac{a_{t+1}}{Q_{t+1} - \gamma Q_t} \right), \quad (17)$$

$$a_t = \Xi_t Z_t (Q_t/Z_t)^{1/\theta_t} n_t(i)^{-1/\theta_t} \quad (18)$$

for all $i \in [0, 1]$, and (16) with equality for all $t = 0, 1, 2, \dots$, where Ξ_t denotes the nonnegative Lagrange multiplier on the aggregate feasibility constraint for period t .

Equation (18) implies that $n_t(i) = n_t$ for all $i \in [0, 1]$ and $t = 0, 1, 2, \dots$, where

$$n_t = (\Xi_t/a_t)^{\theta_t} Z_t^{\theta_t} (Q_t/Z_t).$$

Hence, the social planner finds it optimal to allocate equal amounts of labor to the production of each intermediate good. Substituting this last equation back into the aggregate feasibility constraint yields

$$\Xi = a_t/Z_t$$

for all $t = 0, 1, 2, \dots$. Hence, using (17), the efficient level of output Q_t varies with the preference shock a_t and the technology shock Z_t according to

$$\frac{1}{Z_t} = \frac{1}{Q_t - \gamma Q_{t-1}} - \beta \gamma E_t \left[\left(\frac{a_{t+1}}{a_t} \right) \left(\frac{1}{Q_{t+1} - \gamma Q_t} \right) \right] \quad (19)$$

for all $t = 0, 1, 2, \dots$, an expression that also confirms that here, as in Clardia, Gali, and Gertler (1999), the efficient level of output does not depend on the cost-push shock θ_t . The efficient level of output defined implicitly by (19) then implies a corresponding definition for the output gap x_t as

$$x_t = Y_t/Q_t \quad (20)$$

for all $t = 0, 1, 2, \dots$.

1.7 Symmetric Equilibrium

In a symmetric equilibrium, all intermediate-goods-producing firms make identical decisions, so that $Y_t(i) = Y_t$, $h_t(i) = h_t$, $D_t(i) = D_t$, and $P_t(i) = P_t$ for all $i \in [0, 1]$ and $t = 0, 1, 2, \dots$. In addition, the market-clearing conditions $M_t = M_{t-1} + T_t$ for money and $B_t = B_{t-1} = 0$ for bonds must hold for all $t = 0, 1, 2, \dots$. After imposing these equilibrium conditions and using (5), (7), (10), and (12) to solve out for W_t , M_t , h_t , and D_t , 11 of the remaining equations, (1), (3), (4), (6), (9), (11), (13)–(15), (19), and (20), form a system determining the equilibrium behavior of the 11 variables Y_t , C_t , π_t , r_t , g_t , Q_t , x_t , Λ_t , a_t , θ_t , and Z_t . Some of the real variables in this system inherit unit roots from the random walk (11) in the technology shock. However, the transformed variables $y_t = Y_t/Z_t$, $c_t = C_t/Z_t$, $q_t = Q_t/Z_t$, $\lambda_t = Z_t \Lambda_t$, and $z_t = Z_t/Z_{t-1}$ remain stationary, and the system can be rewritten in terms of these stationary variables.

The transformed system implies that in the absence of shocks, the economy converges to a steady-state growth path, along which all of the stationary variables are constant, with $y_t = y$, $c_t = c$, $\pi_t = \pi$, $r_t = r$, $g_t = g$, $q_t = q$, $x_t = x$, $\lambda_t = \lambda$, $a_t = a$, $\theta_t = \theta$, and $z_t = z$ for all $t = 0, 1, 2, \dots$. The transformed system can therefore be log-linearized around its steady state in order to describe how the economy responds to shocks. Let $\hat{y}_t = \ln(y_t/y)$, $\hat{c}_t = \ln(c_t/c)$, $\hat{\pi}_t = \ln(\pi_t/\pi)$, $\hat{r}_t = \ln(r_t/r)$, $\hat{g}_t = \ln(g_t/g)$, $\hat{q}_t = \ln(q_t/q)$, $\hat{x}_t = \ln(x_t/x)$, $\hat{\lambda}_t = \ln(\lambda_t/\lambda)$, $\hat{a}_t = \ln(a_t/a)$, $\hat{\theta}_t = \ln(\theta_t/\theta)$,

and $\hat{z}_t = \ln(z_t/z)$ denote the percentage deviation of each stationary variable from its steady-state level. A first-order Taylor approximation to (1) reveals that $\hat{c}_t = \hat{y}_t$; since price adjustment costs are of second order according to the quadratic specification, consumption and output are equal to a first-order approximation. First-order approximations to the remaining ten equations then imply

$$\hat{a}_t = \rho_a \hat{a}_{t-1} + \varepsilon_{at}, \quad (21)$$

$$(z - \beta\gamma)(z - \gamma)\hat{\lambda}_t = \gamma z \hat{y}_{t-1} - (z^2 + \beta\gamma^2)\hat{y}_t + \beta\gamma z E_t \hat{y}_{t+1} \\ + (z - \beta\gamma\rho_a)(z - \gamma)\hat{a}_t - \gamma z \hat{z}_t, \quad (22)$$

$$\hat{\lambda}_t = \hat{r}_t + E_t \hat{\lambda}_{t+1} - E_t \hat{\pi}_{t+1}, \quad (23)$$

$$\hat{e}_t = \rho_e \hat{e}_{t-1} + \varepsilon_{et}, \quad (24)$$

$$\hat{z}_t = \varepsilon_{zt}, \quad (25)$$

$$(1 + \beta\alpha)\hat{\pi}_t = \alpha\hat{\pi}_{t-1} + \beta E_t \hat{\pi}_{t+1} - \psi \hat{\lambda}_t + \psi \hat{a}_t + \hat{e}_t, \quad (26)$$

$$\hat{r}_t - \hat{r}_{t-1} = \rho_\pi \hat{\pi}_t + \rho_g \hat{g}_t + \varepsilon_{rt}, \quad (27)$$

$$\hat{g}_t = \hat{y}_t - \hat{y}_{t-1} + \hat{z}_t, \quad (28)$$

$$0 = \gamma z \hat{q}_{t-1} - (z^2 + \beta\gamma^2)\hat{q}_t + \beta\gamma z E_t \hat{q}_{t+1} + \beta\gamma(z - \gamma)(1 - \rho_a)\hat{a}_t - \gamma z \hat{z}_t, \quad (29)$$

and

$$\hat{x}_t = \hat{y}_t - \hat{q}_t \quad (30)$$

for all $t = 0, 1, 2, \dots$ where, in (24) and (26), the cost-push shock $\hat{\theta}_t$ has been renormalized as $\hat{e}_t = -(1/\phi)\hat{\theta}_t$ and the new parameters ρ_e and ψ have been defined as $\rho_e = \rho_\theta$ and $\psi = (\theta - 1)/\phi$ so that ε_{et} is normally distributed with mean zero and standard deviation $\sigma_e = \sigma_\theta/\phi$.

Within the linearized system, (22) defines the marginal utility of consumption in terms of past, present, and expected future output in this model with habit formation in preferences. In light of this definition, (23) becomes a version of the New Keynesian IS Curve, linking past, present, and expected future output to the real interest rate. Equation (26) depicts a version of a New Keynesian Phillips Curve, with partially

backward- and forward-looking components introduced through the indexation parameter α ; the equation indicates that in this specification, $\hat{a}_t - \hat{\lambda}_t$ measures the real marginal cost of production and the renormalized cost-push shock \hat{e}_t impacts directly on inflation. Equation (27) simply rewrites the monetary policy rule, (28)–(30) define the growth rate of output, the efficient level of output, and the output gap, and (21), (24), and (25) repeat the log-linear laws of motion for the preference, cost-push, and technology shocks.

2. RESULTS

The solution to the 10-equation system, (21)–(30), derived using methods outlined by Blanchard and Kahn (1980) and Klein (2000), links the behavior of three observable, stationary variables—the output growth rate, the inflation rate, and the short-term nominal interest rate—to a vector of unobserved state variables that includes the model's four exogenous shocks. Conveniently, this solution can be written in the form of a state-space econometric model, allowing the Kalman filtering and smoothing algorithms reviewed by Hamilton (1994, ch. 13) and extended by Kohn and Ansley (1983) to accommodate cases like this one where the state vector's one-step-ahead forecast error covariance matrix turns out to be singular (in this case, because with habit formation and price indexation, lagged endogenous variables appear in the state vector) to be used to obtain maximum likelihood estimates of the model's structural parameters and to draw inferences about the behavior of the model's structural disturbances.

Here, this empirical exercise uses quarterly U.S. data running from 1983:1 through 2009:4. The starting point comes after the sharp disinflationary episode that followed the appointment of Paul Volcker as Chairman of the Federal Reserve Board in 1979. Therefore, whereas previous studies including Clarida, Gali, and Gertler (2000), Lubik and Schorfheide (2004), Boivin and Giannoni (2006), Justiniano and Primiceri (2008), and Canova (2009) focus on the regime change in Federal Reserve policy that occurred when Volcker assumed office and that may have contributed to the Great Moderation that followed, the analysis here centers on the period of the Great Moderation itself as well as the Great Recession of 2007–09 that brought that tranquil period in U.S. economic history to its abrupt end.

In these data, output growth gets measured by quarter-to-quarter changes in the natural logarithm of real GDP in chained 2005 dollars, converted to per capita terms using the civilian noninstitutional population ages 16 and over. The inflation rate gets measured by quarter-to-quarter changes in the natural logarithm of the GDP implicit price deflator. And the short-term nominal interest rate gets measured by quarterly averages of daily readings on the 3-month U.S. Treasury bill rate, converted from an annualized yield on a discount basis to a quarterly yield to maturity in order to bring the figures from the data in line with the corresponding variable as it appears in the theoretical model. The figures for real GDP and the deflator are seasonally adjusted;

TABLE 1
MAXIMUM LIKELIHOOD ESTIMATES AND STANDARD ERRORS

Parameter	Estimate	Standard error
γ	0.3904	0.0685

σ_r	0.0014	0.0001

NOTES: The standard errors are computed using the parametric bootstrapping procedure described in the text; no entries are shown for α and ρ_e , as all of the bootstrapped replications pushed the estimates of these parameters up against their lower bound of zero.

the figures for the population and the interest rate are not. All data come from the Federal Reserve Bank of St. Louis FRED database.

The theoretical model has 14 structural parameters describing tastes, technologies, and Federal Reserve policy: $z, \pi, \beta, \gamma, \alpha, \psi, \rho_\pi, \rho_g, \rho_a, \rho_e, \sigma_a, \sigma_e, \sigma_z$, and σ_r . Since the steady-state values of output growth, inflation, and the short-term interest rate in the model are given by $z = g, \pi$, and $r = z\pi/\beta$, values $z = 1.0046$, $\pi = 1.0062$, and $\beta = 0.9987$ fixed prior to estimation work to match the average annualized growth rate of real GDP per capita (1.85%), the average annualized inflation rate (2.50%), and the average annualized 3-month Treasury bill rate (4.93%) in the data with the corresponding steady-state values in the model; in effect, this strategy estimates the other parameters using demeaned data. Also, preliminary attempts to estimate the model led consistently to very small values of the Phillips curve parameter ψ , corresponding to very large costs of nominal price adjustment. Hence, the value $\psi = 0.10$ is also fixed prior to estimation; as explained in Ireland (2004, 2007), this setting for ψ can be interpreted based on the fact that it implies an amount of sluggishness in nominal goods prices equivalent to what is produced by the alternative, but closely related, specification in which price setting takes place in a staggered fashion following Calvo (1983) when each individual good’s price remains fixed, on average, for 3.7 quarters, that is, for a bit less than one year.

Table 1 displays the maximum likelihood estimates of the model’s 10 remaining structural parameters. The estimates $\gamma = 0.3904$ and $\alpha = 0.0000$ indicate that for the 1983–2009 sample, the U.S. data prefer a version of the model with a considerable amount of backward-looking behavior in consumption but completely forward-looking behavior in price setting. The estimates $\rho_\pi = 0.4153$ and $\rho_g = 0.1270$ imply that monetary policy works to stabilize both inflation and output, though the policy response to the nominal variable is stronger. Finally, the estimates $\rho_a = 0.9797$ and $\rho_e = 0.0000$ make preference shocks highly persistent but leave cost-push shocks serially uncorrelated.

The standard errors, also reported in Table 1, come from a parametric bootstrapping procedure based on Efron and Tibshirani's (1993, ch. 6), according to which the estimated model gets used to generate 1,000 samples of artificial data on output growth, inflation, and the interest rate, each of the same length as the actual set of U.S. data. Then, these artificial samples get used to reestimate the model 1,000 times, and the standard errors in Table 1 get computed as the standard deviations of the individual parameter estimates across the 1,000 replications. Conveniently and by construction, therefore, this bootstrapping procedure accounts for both the finite-sample properties of the maximum likelihood estimates and the constraints, like those that require many of the model's structural parameters to be nonnegative or to lie between zero and one, that are imposed during the estimation and would thereby prevent even the asymptotic standard errors from having their conventional, normal distributions.

Most notably, the standard errors reveal that while there is some uncertainty about the true degree of backward-looking behavior in consumption, the data speak rather definitively about the lack of backward-looking behavior in price setting, with essentially all of the bootstrapped replications pushing the estimate of the price indexation parameter α up against its lower bound of zero. The standard errors associated with ρ_π and ρ_g are of modest magnitudes, implying that the monetary policy response to inflation is more important than the policy response to output growth statistically as well as economically. And with the sole exception of σ_a , the parameters describing the persistence and volatility of the model's exogenous disturbances are estimated quite precisely; according to the estimated model, the greatest source of uncertainty concerns the role of preference shocks in driving aggregate fluctuations.

The New Keynesian theory outlined above works to identify structural disturbances in the data based on the dynamic effects that they have on the model's observable variables: output growth, inflation, and the nominal interest rate. Figure 1 illustrates these effects by tracing out the impulse responses of each variable to each shock. To facilitate their interpretation, the graphs express output in levels and inflation and interest rates in annualized terms; the periods measured along the horizontal axes continue to represent quarter years, however.

In particular, the graphs in Figure 1 show that while both the preference and monetary policy shocks act like demand-side disturbances, moving output and inflation in the same direction, the preference shock associates an expansion in output with a rising nominal interest rate, whereas the monetary policy shock associates an increasing interest rate with a disinflationary contraction. The cost-push and technology shocks, meanwhile, both act as supply-side disturbances, moving output and inflation in opposite directions. However, the random walk specification (11) allows the technology shock alone to produce a permanent shift in the level of output. Moreover, the impulse responses show that the cost-push shock impacts more strongly on inflation than on output growth; therefore, under the estimated interest rate rule, an adverse cost-push shock calls forth a monetary policy tightening, that is, an increase in the short-term nominal interest rate. Finally, the impulse responses for the output gap, also shown in Figure 1, confirm that cost-push and monetary shocks, and to a large

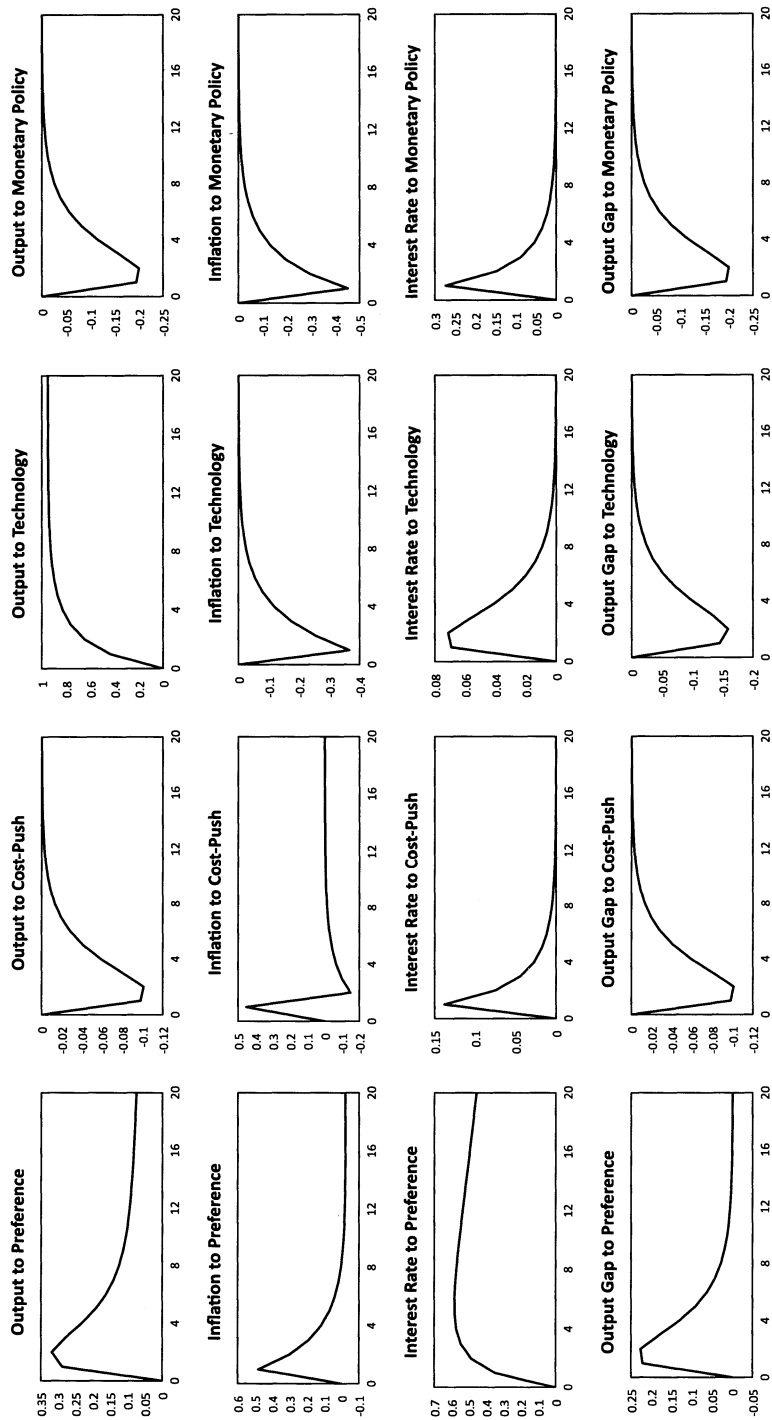

FIG. 1. Impulse Responses.

NOTE: Each panel shows the percentage-point response in one of the model's endogenous variables to a one-standard-deviation innovation in one of the model's exogenous shocks. Output and the output gap are expressed in levels; the inflation and interest rates are in annualized terms. Periods along the horizontal axes correspond to quarter years.

extent preference shocks as well, give rise to inefficient fluctuations in the equilibrium level of output. Following a technology shock, by contrast, equilibrium output does not respond fast enough; as a result, the output gap falls even as output rises following a favorable disturbance.

Table 2 foreshadows many of the additional results that follow by decomposing forecast error variances in the three observable, stationary variables at various horizons into components attributable to the model's four exogenous shocks. Panel A shows that movements in output growth are driven primarily by a combination of preference and technology shocks, with monetary policy shocks playing a smaller but still nonnegligible role. Panel B indicates that movements in inflation, by contrast, are driven in more or less equal measures by all four shocks, while Panel C attributes the bulk of all interest rate movements to preference shocks, except at higher frequencies where monetary policy disturbances also play a key role. Panel D shows variance decompositions for the output gap, too. Because much of the variability in

equilibrium output following technology shocks reflects the economy’s efficient adjustment to those disturbances, most of the variation in the output gap comes from preference and monetary policy—that is, the aggregate demand—shocks.

The numbers in Table 2 reflect movements in output growth occurring throughout the post-1983 sample period, during recoveries and expansions as well as recessions. To identify the fundamental causes of the Great Recession of 2007–09 as well as the two recessions in 1990–91 and 2001 that preceded it, Table 3 reports estimates of the individual shocks occurring during and immediately after those recessionary periods. These estimates of the shocks are smoothed; that is, they rely on information contained in the full sample of data. Important to keep in mind when interpreting

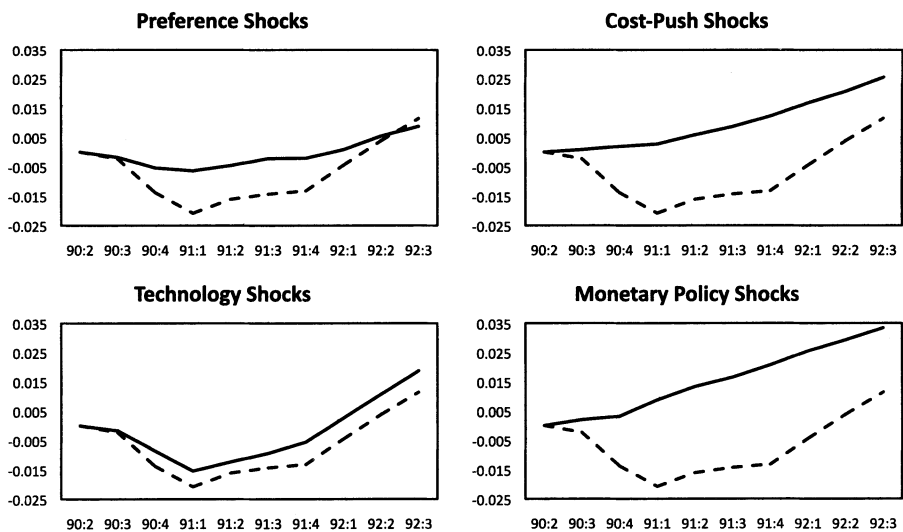

FIG. 2. Counterfactual Output Paths: 1990–91 Recession.

NOTES: Each panel compares the actual path for output (dashed line) with the counterfactual path (solid line) when changes in output are driven by the single shock indicated. Both the actual and counterfactual output paths are expressed as percentage deviations from the level achieved at the cyclical peak just prior to the onset of the recession.

the numbers in Table 3 is the fact that while positive innovations ε_{at} and ε_{zt} to the preference and technology shocks are expansionary, positive cost-push and monetary policy innovations ε_{et} and ε_{rt} lead, according to the impulse responses shown earlier, to declines in output. And to help make clear exactly what constitutes a “large” shock, the maximum likelihood estimates of the standard deviations of each of these four innovations, shown before in Table 1, are reproduced in Panel D at the bottom of Table 3.

Panel A of Table 3 indicates that adverse preference and technology shocks hit the U.S. economy simultaneously at the beginning of the 1990–91 recession. The cost-push shocks remained small throughout this period. And the monetary policy shocks were largely favorable, suggesting that expansionary Federal Reserve policy helped offset at least some of the effects of the adverse preference and technology shocks on output.

Figure 2 leads to the same conclusions in a different way, by comparing the actual path for output, shown by the dashed line as percentage changes from the level reached at the previous cyclical peak, with counterfactual paths, expressed in similar terms by the solid lines, generated when all but one of the structural shocks is “turned off” so as to allow each single shock to operate in isolation. In particular, the graph in the lower left-hand panel of Figure 2 reveals that technology shocks by themselves account for a large fraction of the output lost during the 1990–91 recession. Preference shocks, with effects illustrated in the upper left-hand panel, contributed noticeably to the downturn as well. And the lower right-hand panel confirms that the expansionary

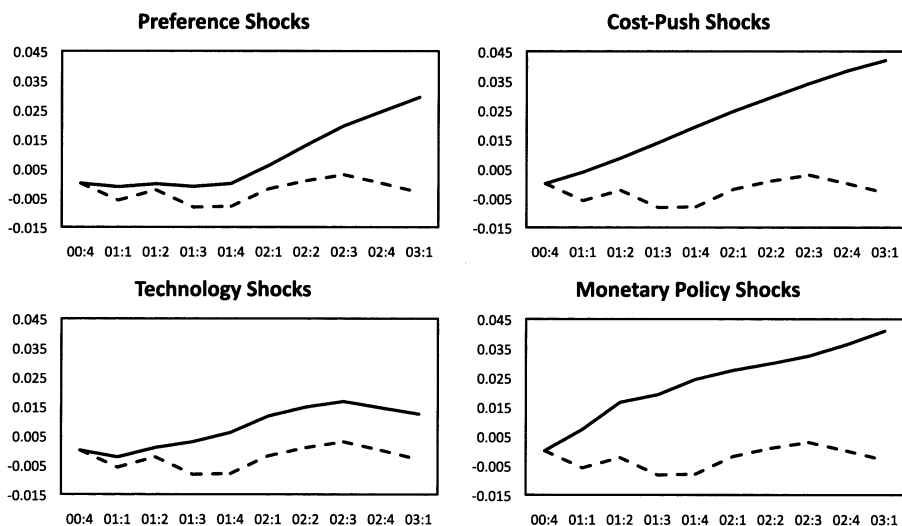

FIG. 3. Counterfactual Output Paths: 2001 Recession.

NOTES: Each panel compares the actual path for output (dashed line) with the counterfactual path (solid line) when changes in output are driven by the single shock indicated. Both the actual and counterfactual output paths are expressed as percentage deviations from the level achieved at the cyclical peak just prior to the onset of the recession.

monetary policy shocks during this period would have worked, by themselves, to generate faster output growth.

Panel B of Table 3 and the graphs in Figure 3 tell a broadly similar story for the 2001 recession. According to the estimated model, a combination of adverse preference and technology shocks caused this recession too, with preference shocks apparently playing a slightly larger role and technology shocks a correspondingly smaller role than before. As in 1990–91, cost-push shocks contribute very little to output movements in 2001, though a series of expansionary monetary policy shocks helped to at least partly offset the decline in output caused by the preference and technology shocks.

Interestingly, according to Panel C of Table 3 and the graphs in Figure 4, the Great Recession began in late 2007 and early 2008 with a series of adverse preference and technology shocks in roughly the same mix and of roughly the same magnitude as those that hit the United States at the onset of the previous two recessions. Likewise, in late 2007 and early 2008, just as before, expansionary Federal Reserve policy, manifested in a series of favorable monetary policy shocks, worked to help insulate the U.S. economy from the full effects of the other disturbances.

The string of adverse preference and technology shocks continued, however, throughout 2008 and into 2009. Moreover, these shocks grew larger in magnitude, adding substantially not just to the length but also to the severity of the great recession. The pattern of shocks generating the most recent recession also departed from patterns from the previous downturns in late 2008 and 2009, when according

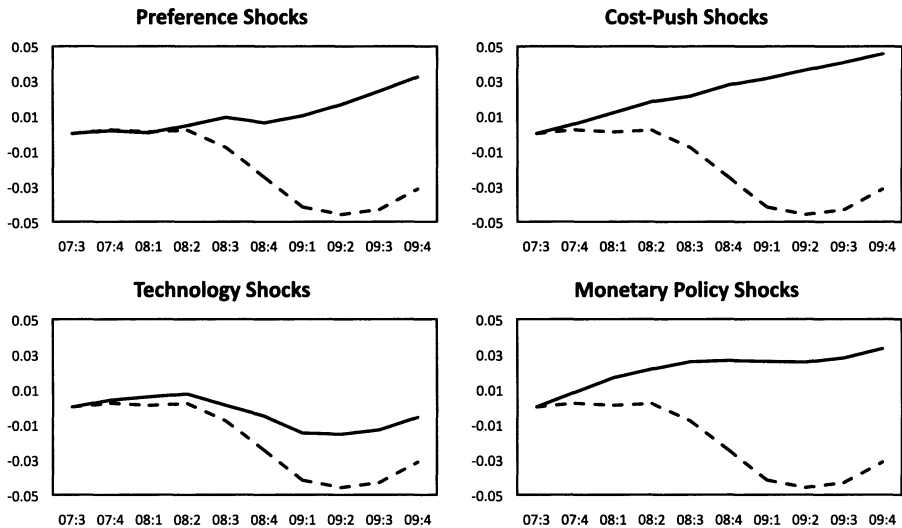

Fig. 4. Counterfactual Output Paths: 2007–09 Recession.

NOTES: Each panel compares the actual path for output (dashed line) to the counterfactual path (solid line) when changes in output are driven by the single shock indicated. Both the actual and counterfactual output paths are expressed as percentage deviations from the level achieved at the cyclical peak just prior to the onset of the recession.

to Panel C of Table 3, monetary policy turned from being mildly expansionary to highly restrictive. These monetary policy shocks, well over two standard deviations in magnitude, resulted, of course, from the zero lower bound on the short-term nominal interest rate, which became binding during the Great Recession but not during the two shorter and milder recessions that preceded it. In particular, the zero lower bound prevented the Federal Reserve from lowering interest rates in response to declining inflation and output in accordance with the estimated monetary policy rule.

To isolate further the effects of the zero lower bound during the Great Recession, Figure 5 compares the actual paths for output and the short-term nominal interest rate (shown by the dashed lines, for output again as percentage changes from the previous cyclical peak and for the interest rate in annualized terms) to counterfactuals (shown in similar terms by the solid lines) generated under an alternative scenario. Whereas, in Figure 4, each of the four shocks is allowed to operate in isolation with the remaining three shut off, in Figure 5 a single shock—the monetary policy shock—is zeroed out while allowing the preference, cost-push, and technology shocks all operate on output and the interest rate as just they did historically.

The bottom panel of Figure 5, therefore, reveals that if the Fed had not faced the binding constraint, it would have continued to follow the estimated Taylor rule by lowering the short-term interest rate another 100 basis points during late 2008 and 2009. The top panel of Figure 5 then indicates that had the Fed left room for this additional monetary policy easing—say by setting a target for inflation 100 basis points higher than its actual (though implicit) target—the U.S. economy would have

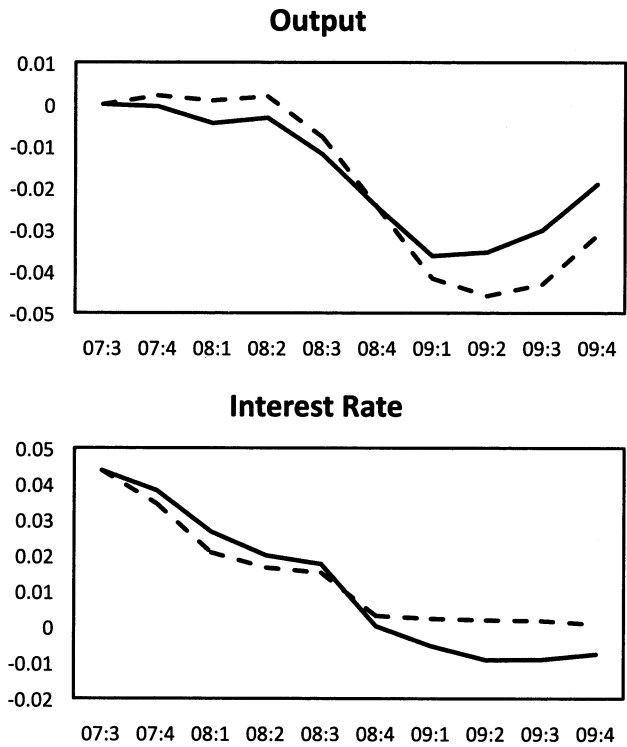

FIG. 5. Counterfactual Output and Interest Rate Paths: 2007–09 Recession.

NOTES: Each panel compares the actual path (dashed line) for output or the interest rate to the counterfactual path (solid line) when no monetary policy shocks occur. Output is expressed as a percentage deviation from the level achieved at the previous cyclical peak. The interest rate is expressed in annualized terms.

bottomed out in the first quarter of 2009 and been well on its way to recovery by the year’s end.

Taylor (2007) argues that Federal Reserve officials, by failing to raise interest rates quickly enough following the 2001 recession, mistakenly adopted an overly expansionary monetary policy from 2002 through 2006 that fueled the excessive boom in housing markets and thereby set the stage for the collapse that followed. To address this hypothesis using the model estimated here, Figure 6 plots the entire series for the smoothed estimates of the monetary policy shocks ε_{π} , joining the numbers shown in the far right-hand side column of Table 3 to those from the rest of the sample period running from 1983:1 through 2009:4.

During the specific period from 2002:2 through 2006:3 discussed by Taylor, the average realization of ε_{π} turns out to be 0.0002, small but positive, and indicative of a monetary policy that erred, if at all, toward being too restrictive, not too easy. One important difference between the benchmark policy rule used by Taylor (2007) and the one used here, however, involves the presence of the change in the interest rate,

FIG. 6. Full-Sample Estimates of Monetary Policy Shocks.

NOTES: The graph shows smoothed (full-sample) estimates of the innovations to the model's interest rate rule for monetary policy.

as opposed to the interest rate itself, on the left-hand side of (14). This difference implies that the dynamics that Taylor interprets as being driven by serially correlated monetary policy shocks are reinterpreted here as reflecting the Federal Reserve's regular tendency to smooth interest rate changes over time. Rudebusch (2002) and English, Nelson, and Sack (2003) discuss the difficulties involved in distinguishing between interest rate smoothing and serially correlated errors in estimated versions of the Taylor (1993) rule; the results obtained here and in Taylor (2007) suggest, however, that resolving these difficulties will be crucial to any effort to evaluate Federal Reserve policy over the past decade. Curiously, Figure 6 points to the early 1990s as a period when Federal Reserve policy appears to have shifted, persistently, from greater accommodation toward greater restraint. Finally, Figure 6 serves to emphasize once again how the zero lower bound forced monetary policy to become extremely restrictive, inhibiting the economic recovery, in 2009.

3. CONCLUSION

In terms of its macroeconomics, was the Great Recession of 2007–09 really that different from what came before? The results derived here from estimating and simulating a New Keynesian model provide the answer: partly yes and partly no.

These results suggest that largely, the pattern of exogenous demand and supply disturbances that caused the Great Moderation to end and the Great Recession to begin was quite similar to the patterns generating each of the two previous downturns in 1990–91 and 2001. Compared to those from previous episodes, however, the series of adverse shocks hitting the U.S. economy most recently lasted longer and became more intense, contributing both to the exceptional length and severity of the Great Recession.

The length and severity of the Great Recession then caused Federal Reserve policy to run up against the zero lower bound on the short-term nominal interest rate, a new problem that had not been encountered before. And so, whereas monetary policy worked according to the estimated model in late 2007 and early 2008 to help insulate the economy from the full effects of the adverse shocks, just as it did throughout the previous two recessions, it added to and prolonged the recession once constrained by the zero lower bound in late 2008 and 2009.

All of these results indicate that the basic New Keynesian model continues to serve as a reliable guide for business cycle analysis and monetary policy evaluation. Indeed, it would be interesting, as a next step, to investigate how the implications of the small-scale model used here would compare to those generated by more elaborate models, especially those that build on the New Keynesian framework, either following Bernanke, Gertler, and Gilchrist (1999) and Iacoviello (2005) among others by incorporating credit market frictions of the kind that have been popularly viewed as important in light of widespread distress in the financial sector during the Great Recession or following Belongia and Ireland (2010) by including explicit roles for bank reserves, currency, and bank deposits as alternative sources of liquidity and thereby expanding the channels of monetary policy transmission beyond the single, interest rate channel that is present here. Since, in particular, the small-scale model estimated here interprets the shocks impacting on the U.S. economy during the Great Recession as having attributes of disturbances to both aggregate demand and aggregate supply, such extensions might provide a more detailed view of how disruptions in markets for real and financial assets affect households and businesses' willingness and ability to spend and, at the same time, distort the allocation of productive resources across competing uses.

Finally, the results derived here point to the need for a more complete and detailed assessment of monetary policymaking strategy in light of the problems caused by the zero lower bound on the short-term nominal interest rate during the most recent recession. Goodfriend (2000) suggests several possible maneuvers that central banks might use to circumvent the zero lower bound constraint, including charging negative interest rates on—that is, taxing—banks' holdings of reserves and the nonbank public's holdings of currency as well as conducting open market purchases of long-term U.S. Treasury securities, all of which deserve further consideration in the context of New Keynesian specifications that extend the one used here. Following Taylor (2007), actual Federal Reserve policy both during and in the years leading up to the Great Moderation could also be compared to optimal monetary policy as identified by New Keynesian models, so as to better pinpoint past mistakes, if any, that might be avoided in the future. As noted above, such an exercise would necessarily involve an attempt to distinguish, perhaps using methods suggested by Rudebusch (2002) and English, Nelson, and Sack (2003), serially correlated shocks to the Federal Reserve's interest rate rule from the inertia generated by the Fed's regular interest rate smoothing procedures. Such an exercise would also have to confront more seriously the result obtained here that a significant component, not just of the Great Recession but of the previous recessions in 1990–91 and 2001 as well, gets attributed by the

estimated model to technology shocks, implying that monetary policy's role is limited to helping the economy respond efficiently to, as opposed to insulating the economy from, the effects of those supply-side disturbances. Put in the broadest of terms, the results obtained here underscore that the questions first raised by Kydland and Prescott (1980), regarding the extent to which public policy can and should be used for economic stabilization, loom as large in macroeconomics today, in the immediate aftermath of the Great Recession, as they did three decades ago.
